Paula Stern, BSc, DC, FCCS(C)¹

Osteoporosis often results in fractures, deformity and disability. A rare but potentially challenging complication of osteoporosis is a sternal insufficiency fracture. This case report details a steroid-induced osteoporotic male who suffered a sternal insufficiency fracture after minimal trauma. Prompt diagnosis and appropriate management resulted in favourable outcome for the fracture, though a sequela involving a myocardial infarction ensued with his osteoporosis and complex health history. The purpose of this case report is to heighten awareness around distinct characteristics of sternal fractures in osteoporotic patients. Discussion focuses on the incidence, mechanism, associated factors and diagnostic challenge of sternal insufficiency fractures. This case report highlights the role primary contact practitioners can play in recognition and management of sternal insufficiency fractures related to osteoporosis.

Key words: sternal fracture, osteoporosis, insufficiency fracture

Introduction

Osteoporosis affects approximately 1.4 million Canadians, mainly postmenopausal and elderly individuals. Patients with one or more vertebral fractures are 4-5 times more likely to have a subsequent vertebral fracture. There is also significant risk for fractures at the hip and wrist, leading to further disability and increased economic burden to society. Authors have proposed that sternal fractures, a rare complication of osteoporosis, are not well understood. Pathogenesis of this condition in osteoporotic patients, and its impact on subsequent fracture risk and overall health, is unclear. Although the clinical presentation and management of isolated sternal fractures are well known in the general population, they may have distinct characteristics in those with osteoporosis, making it difficult for recognition and management among primary contact providers.

This case report (event timeline outlined in Table 1) describes a steroid-induced osteoporotic patient, with a history of multiple vertebral compression fractures, suffering a sternal insufficiency fracture, and later experiencing a complex sequelae involving a myocardial infarction (MI) related to his osteoporosis and co-morbidities. The incidence, mechanism, associated factors and diagnostic characteristics of sternal fractures in the osteoporotic population will be discussed. In light of the MI that occurred in this patient’s long-term follow-up, the case also discusses the potential relationship between MI and low bone mineral density (BMD) with osteoporosis.

Case Report

A 56 year-old steroid-induced osteoporotic male presented to his orthopaedic surgeon for post-operative follow-up. Ten weeks prior to this follow-up appointment, he had recurrent back pain diagnosed as vertebral compression fractures, for which he received two-stage kyphoplasty to T12, L1 and L4 (first stage), and L2, L3 and L5 (second stage), completed two days apart. The patient reported immediate improvement in pain and was discharged the next day after an uneventful post-operative course. He was given oxycodone/acetaminophen and scheduled for follow-up in 6-8 weeks. His medical history was remarkable for asthma, chronic obstructive pulmonary disease, rheumatoid arthritis, multiple previous chest infections and previous compression fractures (treated with kyphoplasty at T9, T10, and T11). His long-standing use of medications consisted of methylprednisone for rheumatoid arthritis (4 mg once daily, patient titrated as needed); albuterol (four puffs 4 times daily, and every 2 hours as needed), budesonide (two puffs 2 times daily), budesonide/formoterol inhaler (two puffs 2 times daily), and ipratropium bromide inhaler (two puffs 4 times daily) for asthma and chronic obstructive pulmonary disease; a course of alendronic acid/colecaciferol (had completed course of teriparatide), calcium and vitamin D for osteoporosis. The patient was a non-smoker with no personal/family history of coronary artery disease.

At follow-up with the orthopaedic surgeon, his pain from compression fractures was significantly reduced, but he was now presenting with anterior midline chest and upper thoracic pain of two weeks’ duration that started after reaching into the refrigerator. Presenting after minimal trauma, the pain was localized to mid-sternum and midline upper thoracic spine. No neurological symptoms were reported. At this time, the patient was not taking any medication for the pain. On physical examination, severe anterior head carriage and thoracic kyphosis was noted, visually estimated to be 70-80 degrees of thoracic kyphosis with the curve apex at the mid-thoracic spine.

level. The patient used a cane minimally and was slow in ambulation due to postural imbalances related to his severe kyphosis. Light palpation of mid-sternum in the anterior-to-posterior direction revealed crepitation and reproduced the chest pain. Sternal radiographs revealed a fracture subluxation with slight step deformity in mid-portion of the sternum, corresponding to the painful area clinically (Figure 1). Thoracic radiographs revealed no new fractures in the upper thoracic spine (Figure 2). Since the sternal fracture was evident on radiograph and clinically correlated with his symptoms, a diagnosis of sternal fracture was given and no additional tests were ordered at the time. The isolated sternal fracture was managed conservatively with oxycodone (1-2 tablets every 4-6 hours

Figure 1: Lateral spot-view radiograph of the sternum reveals fracture of the sternal body. There is interval development of a new fracture in the proximal portion of the sternal body (arrow).

Figure 2: Lateral thoracolumbar radiograph reveals previous kyphoplasty procedures at T9, T10, T11, T12, L1, L2, L3, L4 and L5. Contrast agents are confined to the vertebral bodies with no significant leaks. Old compression fractures suspected at T7 and T8. There is generalized decrease in bone density and multilevel degenerative changes.
as needed), acetylsalicylic acid (325 mg once daily for 30 days, then 81 mg once daily) and monitoring.

With monitoring, the sternal fracture pain improved with pain medication and clinically resolved after 16-17 weeks. However, the patient experienced recurrent back pain, confirmed as new compression fractures at T7 and T8 at visits with the orthopaedic surgeon, and the pain decreased significantly after kyphoplasty to these segments. Six weeks after kyphoplasty, the patient presented with diffuse pain in the left mid ribs and a recurrence of upper thoracic pain, and watchful waiting was decided upon.

**Long-Term Follow-up:**
Two weeks later, the patient reported midline chest pain 40-60 minutes prior to his arrival to the emergency department, of 8/10 in severity that radiated to his left arm. There was no nausea, vomiting, shortness of breath or diaphoresis. One week prior, the patient went to a walk-in clinic for recurrent left shoulder and arm pain and received pain medication. On examination, the patient was alert, oriented, in no acute distress and able to complete full sentences. Cardiovascular, respiratory, abdominal and neurological examinations were normal. The patient had distal pulses positive and cool extremities bilaterally, but no tender calves or significant edema.

Laboratory results revealed troponin at less than 0.01 and creatine kinase of 36. Chest radiographs found no obvious consolidation or sternal fracture. Echocardiogram and coronary angiography revealed an inferior ST-elevated MI, a 100% occlusion (< 1 mm) of a small distal pulmonary venous branch of right coronary artery and mild inferior hypokinesis. Due to the small occlusion size, the ST-elevated MI was managed with clopidogrel bisulfate, acetylsalicylic acid, heparin, antibiotics and a refill of respiratory medications, while respiratory status was monitored in the coronary care unit. On discharge 2 days later, the patient was neurologically intact, in stable condition and was to continue post-MI management at home with follow-up from his medical doctor, specialists and community care services.

**Discussion**

**Incidence:**
Sternal fractures are rare, with a reported incidence of 0.5% of all bony fractures, and often by major trauma like motor vehicle accidents. Of all sternal fractures presenting to emergency in a 6.5-year timeframe, 92.3% of 272 cases were related to motor vehicle accidents and 7.7% were due to direct sternal trauma. Few reports have documented a sternal fracture in an osteoporotic individual, known as an insufficiency or fragility fracture, which is a stress fracture in bones with decreased mineralization and elastic resistance. In a retrospective survey of all insufficiency fractures except spinal fractures, only one sternal fracture (1.1%) was identified among 91 insufficiency fractures. In a recent review, most sternal insufficiency fractures were due to some form of high or low degree of trauma, such as a fall from standing. However, the sternal fracture in our case was from reaching into a refrigerator, which is considered minimal trauma, occurring 10 weeks after kyphoplasty was performed for multiple compression fractures. This warrants a closer investigation on the role osteoporosis may have on the sternum.

**Mechanism and Associated Factors:**
While the etiology of sternal insufficiency fractures is not well understood, generalised bone changes in osteoporosis plays an important role. Trabecular bone changes during osteoporosis have been shown to increase risk for subsequent fractures. Known as the fracture cascade phenomenon of osteoporosis, this may occur in sites other than the spine, but to a lesser extent. For example, a vertebral fracture also increases the risk of subsequent hip fracture by 3-fold. Histomorphometric bone analyses from iliac crest have reportedly found anistrophic trabecular changes in individuals with osteoporotic vertebral fractures, including fewer trabeculae, greater trabecular spacing, lower osteocyte density and reduced cortical thickness. Since the sternum is a flat bone comprised of two thin layers of compact bone surrounding trabecular bone, it may be susceptible to such microarchitectural disruption.

Biomechanical factors may compound trabecular effects and increase fracture risk. Some propose that increased thoracic kyphosis from compression fractures transfer axial force loads from spine to sternum and increases fracture risk. A recent dynamic systems model describes multidimensional risk factors to osteoporotic fractures, including altered bone quality and density, local and global spine changes, and aberrant biomechanics. While load transference in biomechanics is discussed in this model, its impact on bony structures anteriorly, such
as the sternum, is not considered; the model is limited to changes along the spine and paraspinal musculature. This case report sheds further light on this cascade and may suggest the need for a broader anatomical perspective when considering altered biomechanics and trabecular changes in osteoporosis.

In this patient, a number of factors may have contributed to the sternal fracture. In addition to his severe thoracic kyphosis and longstanding osteoporosis, the patient had a two-stage kyphoplasty procedure 10 weeks prior to the sternal insufficiency fracture, where he laid prone on a surgical table that supported the weight of his chest through a padded horizontal chest bolster across the sternum. In subsequent kyphoplasties, the placement of bolsters on the surgical bed was changed to two vertical bolsters from the iliac crest to the shoulders to prevent direct pressure on his sternum. For patients undergoing kyphoplasty and had previously suffered a sternal insufficiency fracture, this simple, no-cost repositioning of the surgical table bolsters may be indicated to decrease pain and risk of further complications at the sternal fracture site.

Clinical Presentation and Significance:
The variable clinical presentation of sternal fractures can be a diagnostic challenge in differentiating it from other conditions. Chen reported that in 7 cases of sternal insufficiency fractures, 2 buckling fractures were asymptomatic while 5 non-buckling fractures were painful. However, Min and Sung reported that 5 of 7 patients with buckling sternal fracture had chest pain. Two previous cases also presented with such severe anterior chest pain that they were suspected as myocardial infarctions. Our patient complained of moderately intense anterior chest pain of two weeks duration, noted as local tenderness and crepitus during sternal palpation. A clinical index of suspicion for sternal fracture allowed for appropriate management, which involved sternal radiographs to confirm the diagnosis. Although sternal fractures as a complication of osteoporosis are relatively rare, it should be recognized that clinical presentation can range from asymptomatic to severe pain and should be a differential diagnosis for osteoporotic patients with chest pain.

Literature is mixed regarding prognosis and calls for differentiation between traumatic and insufficiency fractures. In traumatic cases, it has been suggested that computed tomography should follow radiographs to evaluate the extent of sternal and episternal injuries. However, isolated sternal fractures, likely in the case of insufficiency fractures, have a very good outcome, as sternal fractures alone are reportedly not indicative of significant myocardial, mediastinal or thoracic aorta damage. Our patient’s sternal insufficiency fracture was successfully managed with pain medication, and appeared to have healed within 16-17 weeks from onset.

Long-Term Sequelae of this Case:
Despite the favourable outcome of the sternal insufficiency fracture, the patient had complications related to his osteoporosis and complex health history. Two weeks after his sternal fracture appeared to have healed, he suffered a ST-elevated MI, which required immediate reperfusion therapy to avoid cardiogenic shock, especially within 12 hours of symptom onset and without contraindications. In this case, the recurrent anterior chest pain in our patient was not dismissed as residual pain from the preceding sternal fracture; instead, thorough investigation was conducted to rule out MI. The prompt diagnosis and management within 1 hour of symptom onset enabled the MI to be successfully managed medically with favourable short-term outcome.

Growing literature suggests a significant link between cardiovascular disease and low BMD, particularly between MI and future osteoporotic fracture risk. For instance, lower femoral neck and hip BMD has been significantly associated with increased risk of MI in both men and women, even after adjusting for smoking, hypertension, hypertriglyceridermia and diabetes. Conversely, in a matched cohort study, a substantial increase in fracture risk (in all fracture sites) in survivors of MI was observed, a trend that has markedly increased over the past 3 decades. This population-based study noted an emerging association between MI and the risk of osteoporotic fracture in the community, a novel finding that was not observed in the general population.

Although there are possible confounders to the increased risk of fractures in MI survivors, recent literature suggests that these factors take a smaller role than previously thought. First, vitamin D and calcium supplements have been suggested to increase MI risk. Second, pharmacological agents could play a role, since MI patients often have comorbidities being managed pharmacologically. This includes medications for cardiovascular dis-
ease like heparin, oral anticoagulants and loop diuretics that can lead to drug-induced osteoporosis. However, the well-controlled 30-year longitudinal population-based study by Gerber et al still found a steady increase in osteoporotic fracture risk after MI, even after considering 19 serious comorbid conditions and stratifying for ST-elevated MI individuals who tend to be less frail and healthier. These analyses indirectly argue against the role of certain comorbidities and/or medications as primary explanations for the increase in fracture risk after MI, and emphasize the importance of considering a substantial fracture risk at all fracture sites in osteoporotic MI survivors.

It is important for chiropractors to be aware of potential complications associated with osteoporosis, particularly sternal insufficiency fractures and increased fracture risk after MI, as these patients may present on a monthly or annual basis. In 2010, in a combined online and mail survey of American chiropractors conducted by the National Board of Chiropractic Examiners with 3938 out of 9839 respondents (40% response rate), it was found that 3.7-3.8% of chief complaints from patients were related to chest pain. Although fractures were rarely (1-10x/year) seen by respondents in the past year, osteoporosis was more often seen by respondents, at a rate of 1-3x/month, where 70% of these cases were co-managed. Since sternal fractures in these patients may be biomechanically linked with high degrees of thoracic kyphosis, similar to previous sternal fracture cases with multiple compression fractures and/or severe osteoporosis, these individuals being seen by the chiropractor may be more frail, have more complex health conditions and require participation in secondary prevention programs and physical activity in preventing bone loss and falls.

**Conclusion**

Although rare, sternal insufficiency fractures can present as challenges in the clinical setting, as they have variable clinical presentations and are often biomechanically linked to high degrees of thoracic kyphosis from multiple compression fractures in severe osteoporosis. This case report detailing a sternal insufficiency fracture in an osteoporotic male heightens awareness of their distinct characteristics in the osteoporotic population, aiding diagnosis and management by primary contact providers. In addition, this case report discusses the consideration of an increased fracture risk after a MI in osteoporotic patients, highlighting the integral role chiropractors can play in incorporating fracture prevention strategies in this patient population.
