Objective: To present a case of an os odontoideum and to provide insight into the varied clinical presentations.

Clinical Features: A 54 year old man presented with chronic neck pain without headache. A clinical examination was performed and the chiropractor viewed his AP and lateral radiographs. Previous flexion/extension radiographs and MRI imaging from 2009 were requested for review. The patient was diagnosed with grade II mechanical neck pain. Treatment was rendered that day which included spinal manipulation/mobilization. Several days later the requested imaging reports were received and described the presence of an os odontoideum.

Conclusion: In the presence of os odontoideum, familiarity with the signs and symptoms of potential cervical instability is imperative. Health care providers...
Introduction
Os odontoideum is the most common anomaly of the odontoid process.¹ The term os odontoideum was first coined by Giacomini in 1886 and is defined as “...an os- sicle with smooth circumferential cortical margins and no osseous continuity with the body of C2”.² Debate within the literature continues regarding the congenital or traumatic etiology of os odontoideum. Regardless of etiology, both types of os odontoideum can lead to instability of C1 on C2, placing the spinal cord at significant risk of injury.³ This paper presents a case of os odontoideum in a Fifty-four year old male presenting to a chiropractic clinic with longstanding neck pain. Clinical presentations, diagnosis and management are discussed. Manual therapists treating neck complaints need to be aware of this anomaly considering that instability of the atlanto-axial joint secondary to an os odontoideum can have serious consequences.

Case Presentation
A fifty-four year old male presented to a chiropractic clinic with a longstanding complaint of a stiff and achy neck and upper back without headache. The neck pain was focused primarily on the left and the patient reported significant right rotational restriction, especially with shoulder checking. The patient reported one previous episode of neck pain in 2009 and two previous motor vehicle accidents; a roll-over accident in the 1970s and a minor accident in the 1980s. No medical attention was sought following either accident.

On examination, an alordotic cervical curve was present with mild anterior head carriage. Upper limb neurological screening was unremarkable bilaterally (upper deep ten-
of this area will be helpful to further assess the extent of healing at the fracture line”.

The patient returned to the chiropractic office a few days later and the results of the imaging reports were reviewed. The patient mentioned that the results of the 2009 imaging studies were never discussed with him. The patient was educated on the os odontoideum condition, advised that cervical spine manipulation was no longer a treatment option, and referred back to his medical doctor for further evaluation and surgical considerations. The patient was not seen by an orthopaedic specialist as he was not interested in surgical intervention.

Discussion
The exact incidence and prevalence of os odontoideum is unclear within the literature as many cases remain clinically silent. Considering the issues with instability and the risk of morbidity which arise in patients with os odontoideum, it is imperative that manual therapists are aware of potential clinical indicators of the condition. The clinical presentation of os odontoideum is quite varied within the literature and can differ significantly between patients. Although os odontoideum cannot be diagnosed without the use of imaging, the following clinical presentations have been noted:

Asymptomatic
Many patients with os odontoideum are often delayed in their diagnosis or the os odontoideum is found as an incidental finding on radiographs because patients are often asymptomatic. The majority of asymptomatic individuals are neurologically intact and only some present with incidentally discovered atlanto-axial instability.

Neck Pain
Neck pain is one of the most common symptoms in patients with a diagnosed os odontoideum. In a review of seventy eight patients identified with an os odontoideum, neck pain was the most commonly reported symptom in 64% of patients. It has also been reported that in some cases, pain in the occipital or cervical region may be the only symptom. However, with an already high prevalence of neck pain in the general population and a lack of prospective studies, the link between neck pain and the presence of os odontoideum is a difficult association to make.
Headaches

Headaches, a common condition treated by manual therapists, have been reported as a symptom of os odontoideum in the literature however not to a great extent and mostly within case reports. In a 2011 review of seventy eight patients with os odontoideum, only 2 patients presented with headaches. The estimated lifetime prevalence of headache (including all headache types) has been reported to be between 93% and 98%. Given such a high prevalence of headache in the general population, the association between os odontoideum and headache is unclear.

History of Trauma

The association between os odontoideum and previous history of trauma is debated within the literature. However, a large portion of evidence currently points towards a traumatic etiology in the majority of reported cases. There is a proposed theory that trauma may be an instigating event for the development of symptoms from a pre-existing os odontoideum. In a case series by Spierings and Braakman, approximately 43% of patients presented with a history of trauma. Other authors maintain that previous traumatic events may not be responsible for an os odontoideum. These authors have proposed that a traumatic event could result in a soft tissue injury that may increase the degree of instability and thus cause a pre-existing os odontoideum to become symptomatic. The effect trauma has on developing or exasperating a pre-existing os odontoideum is still unknown. However, given the amount of evidence pointing towards a traumatic etiology, inquiring about previous trauma during a patient history may offer valuable information to warrant further investigation.

Congenital Syndromes

Os odontoideum are commonly associated with a number of congenital syndromes. It is important to keep this differential in mind in patients presenting with Down syndrome, Klippel-Feil syndrome, Morquio’s disease, multiple epiphyseal dysplasia, pseudoachondroplasia, achondroplasia, Larson syndrome, and chondrodystrophy calcificans. It is proposed that ligament hyperlaxity and incomplete ossification of the odontoid process in these syndromes may predispose individuals to the development of a traumatic os odontoideum.

Neurological Signs and Symptoms

Patients with os odontoideum can be asymptomatic however, many have also presented with a wide array of neurological symptoms. In a review of seventy eight patients with os odontoideum, eighteen patients (23%) had neurological signs or symptoms at presentation and an additional fifteen (19%) had a history of intermittent or prior neurological symptoms. Patients with an os odontoideum may have abnormal atlanto-axial motion anteriorly, posteriorly or in both directions. Flexion of the cervical spine can cause anterior translation of C-1 leading to impingement on the dorsal aspect of the spinal cord whereas extension can cause the anterior ring of C1 and ossicle to impinge on the ventral aspect of the cord. Therefore, a wide variety of neurological signs and symptoms may present in patients with os odontoideum ranging from subtle transient myelopathy to more explicit signs such as tetraplegia, paresis, bulbar sign and central cord syndrome.

Recommendations

The proper management of os odontoideum still remains uncertain due to the fact that it is a rare condition. The majority of the literature consists of case reports and case series making it difficult to offer evidence-based guidelines and practice recommendations. Also, there remains a gap in knowledge of the long term natural history of untreated os odontoideum. The majority of reports indicate that patients tend to remain asymptomatic after a follow-up between one and seven years. However, one study reported that symptomatic atlanto-axial instability can develop over time, even after a diagnosis of a ‘stable’ os odontoideum is made.

The following recommendation has been given for patients with incidental os odontoideum: “Patients with os odontoideum, either with or without C1–2 instability, who have neither symptoms nor neurological signs may be managed with clinical and radiographic surveillance. However, other authors have advocated for surgical intervention for all patients with radiographically unstable os odontoideum, whether symptomatic or not. Although there are inconsistencies within the literature and a lack of high quality evidence, Table 1 lists recommendations that have been noted within the literature.
Conclusion
There remains a lack of consensus within the literature regarding best practices for os odontoideum and the long term prognosis is unknown. With this uncertainty and the risk of cervical instability, it is imperative that health care professionals, particularly manual therapists who treat neck pain patients, become familiar with the signs and symptoms of potential cervical instability. These health care providers must also remain diligent in their patient histories, physical exams, and imaging studies. This case highlights the importance of following up on imaging studies to rule out diagnoses and not simply relying on the fact that they were performed. Whether or not surgical fixation is warranted is outside the scope of practice for manual therapists. However, the role of manual therapists should be to recognize signs and symptoms of os odontoideum, refer patients for a medical opinion and surgical consultation, and properly educate their patients on the nature and potential risks of their condition.

References

Table 1.
Recommendations for os odontoideum

- A detailed history, physical exam and neurological exam should be completed on all neck pain patients to look for clinical indicators of instability and detect subtle myelopathies.3
- If instability is suspected, initial imaging should include cervical radiographs consisting of an open-mouth odontoid view, a lateral cervical view and flexion/extension views.3,4
- An unstable os odontoideum is an absolute contraindication to cervical spine manipulation and possibly cervical spine mobilization.11
- Atlanto-axial instability has been defined as greater than three millimeters of motion at C1-C2 on flexion/extension films.12
- A MRI and surgical consultation is indicated if significant instability is seen on flexion/extension radiographs or if myelopathy is detected on clinical examination.3,4,13
- All patients with an os odontoideum should be educated on potential instability.2
- Patients deemed ‘stable’ upon surgical consult or who choose not to undergo surgery are encouraged to have flexion-extension radiographs taken every year and a MRI of the cranio-cervical junction every five years. These patients should also be educated regarding the risks of participation in contact sports.8
