Case Presentation
An 80-year-old white male presented to a chiropractic clinic with a 3-year history of insidious and progressing neck stiffness and “cramping,” increased difficulty turning his head from side-to-side (e.g. while driving), and a “choking” sensation when flexing his neck. He also complained of a constant pressure in his throat as well as difficulty swallowing his saliva, to the point where he felt like he was “choking on his spit at times.” He had no problems with normal breathing, speaking, or swallowing food and he denied any symptoms suggestive of cervical radiculopathy or myelopathy. The only difficulty he reported with eating was an “inability to look down at the plate to see his food.” On examination, his cervical spine range of motion was severely limited (by 80-90%) in all directions. Flexing his neck forward beyond five degrees would elicit asphyxia. Bilateral upper limb neurologic examination, including motor, reflex, and sensory testing, was unremarkable. Cervical spine radiographs revealed complete bilateral ossification of the stylohyoid ligaments as well as advanced ossification of the anterior longitudinal ligament (flowing hyperostosis) throughout the cervical and upper thoracic spine, abutting and displacing the prevertebral soft-tissues (Figures 1-3). Based on these findings, the patient was diagnosed with Eagle syndrome and diffuse idiopathic skeletal hyperostosis (DISH).

Discussion
Symptomatic elongation of the styloid process and/or ossification of the stylohyoid ligament was first described by Eagle1,2 in the late 1940s and is known as Eagle syndrome. Elongated styloid processes or ossified stylohy-
oid ligaments can be palpated intraorally along the tonsillar pillars and radiographic imaging usually confirms the diagnosis.1-3 Anatomically, these bony structures can compress or irritate the surrounding neurovascular soft-tissues in the neck, namely the internal carotid artery and the trigeminal, facial, glossopharyngeal, and vagus nerves. Patients may present with an array of symptoms although many with elongated styloid processes or ossified stylohyoid ligaments will also remain asymptomatic.3,4 Table 1 lists the key imaging and clinical features for Eagle syndrome and Table 2 lists the key imaging features of DISH. Symptomatic patients with Eagle syndrome can be treated surgically or non-surgically.3,5,6 Chiropractors and other manual therapy providers should note, however, that elongated styloid processes or ossified stylohyoid ligaments may pose a relative contraindication to thrust manipulation of the cervical spine.7 For instance, an association between styloid process length and risk of cervical carotid artery dissection has been reported.8 Surgical treatment for Eagle syndrome typically involves styloid process shortening or resection.3,5

The etiology of Eagle syndrome is still controversial but it is thought to result from post-surgical (e.g. tonsillectomy) or traumatic (e.g. styloid fracture) scarring.1-3 There is some evidence to suggest that there may also be a correlation between ossification of the stylohyoid ligaments and ligamentous ossification of the cervical spine in patients with DISH.4 This combination of findings is unique, however, in that very few cases involving both Eagle syndrome and DISH have been described in the literature.4,9 As such, further investigation is needed in order to validate this association.

In the current case, the patient consulted his primary care physician and no further diagnostic testing or surgical treatment was recommended. A course of conservative care, including neck mobilizations (i.e. cervical flexion-distraction / decompression therapy) and instru-

ment-assisted soft-tissue massage (i.e. Graston® Technique), was implemented. The soft-tissues treated included the cervical paraspinals, scalenes, upper trapezius, and levator scapulae muscles, bilaterally. After seven visits (over 10 weeks), the patient reported a mild decrease in neck pain and stiffness but continued to have symptoms of “chooking” and asphyxia, particularly with neck flexion. It is unknown if these symptoms were a result of Eagle syndrome, DISH, or a combination of both. Several cases of dysphagia and airway obstruction in relation to DISH and/or Eagle syndrome have been reported.\(^9,10\) In the current case, an upper G-I fluoroscopic (barium swallow) study could have been performed in order to more definitively ascertain the cause of the patient’s oropharyngeal symptoms. Regardless, the clinical findings of neck pain, throat irritation, mild dysphagia, and ossified stylohyoid ligaments were compatible with a diagnosis of Eagle syndrome. For more information and additional examples of Eagle syndrome, visit Radiopaedia.org.\(^11\)

### Key Messages

- Published cases involving Eagle syndrome and DISH of the cervical spine are rare
- The differential diagnosis of patients who present with dysphagia, a sensation of a foreign body in the throat, pain in the distribution of the carotid arteries, and/or neuralgia involving cranial nerves 5, 7, 9, and 10 should include Eagle syndrome
- Patients with this disorder can be treated surgically or non-surgically, however there is a relative contraindication to thrust manipulation of the cervical spine
